Introduction: Objective markers for asthma, that can be measured without extra patient effort, could mitigate current shortcomings in asthma monitoring. We investigated whether smartphone-recorded nocturnal cough and sleep quality can be utilized for the detection of periods with uncontrolled asthma or meaningful changes in asthma control and for the prediction of asthma attacks.

Methods: We analyzed questionnaire and sensor data of 79 adults with asthma. Data were collected in situ for 29 days by means of a smartphone. Sleep quality and nocturnal cough frequencies were measured every night with the Pittsburgh Sleep Quality Index and by manually annotating coughs from smartphone audio recordings. Primary endpoint was asthma control assessed with a weekly version of the Asthma Control Test. Secondary endpoint was self-reported asthma attacks.

Results: Mixed-effects regression analyses showed that nocturnal cough and sleep quality were statistically significantly associated with asthma control on a between- and within-patient level ($p < 0.05$). Decision trees indicated that sleep quality was more useful for detecting weeks with uncontrolled asthma (balanced accuracy (BAC) 68% vs 61%; Δ sensitivity -12% ; Δ specificity -2%), while nocturnal cough better detected weeks with asthma control deteriorations (BAC 71% vs 56%; Δ sensitivity 3%; Δ specificity -34%). Cut-offs using both markers predicted asthma attacks up to five days ahead with BACs between 70% and 75% (sensitivities 75 - 88% and specificities 57 - 72%).

Conclusion: Nocturnal cough and sleep quality have useful properties as markers for asthma control and seem to have prognostic value for the early detection of asthma attacks. Due to the limited study duration per patient and the pragmatic nature of the study, future research is needed to comprehensively evaluate and externally validate the performance of both biomarkers and their utility for asthma self-management.

Keywords: asthma, digital biomarker, nocturnal cough, sleep quality, asthma control assessment, asthma attack prediction

Introduction

Asthma is one of the most prevalent chronic respiratory diseases. It affects an estimated 300 million people globally.¹ Despite the availability of effective treatment options, suboptimal asthma control is still common.^{2,3}

To prevent potentially life-threatening asthma attacks, patients need to be aware of their actual asthma control and early warning signs of deterioration.² However, prior research has found that patients' subjective self-assessments are biased towards an overestimation of asthma control.⁴ For patients with a longer duration of illness, in particular, subjective assessments are of limited reliability.⁵ Furthermore, objective methods of asthma monitoring (eg, self-administered asthma control test (ACT)⁶ or

peak flow monitoring) are considered impractical by patients⁷ and are still poorly adopted in practice.⁴

Novel objective markers, that can be measured without extra patient effort, could mitigate these shortcomings.⁸ Nocturnal cough and sleep quality, for example, have been reported to be statistically associated with asthma control in cross-sectional studies.^{9–11} Research in the domain of mobile sensing demonstrated their measurability by means of a smartphone's built-in sensors.^{12,13}

We investigated whether nocturnal cough and sleep quality may constitute useful markers for asthma. Expanding the findings of prior research, we first examined whether both markers are associated with asthma control in a longitudinal (ie, within-patient) setting. We then investigated whether both markers can enable the detection of periods with uncontrolled asthma or clinically meaningful deteriorations of asthma control, and prediction of asthma attacks.

Methods

The study protocol of this two-center, longitudinal, observational study has already been published¹⁴

(Clinicaltrials No: NCT03635710). Here, we report results on the association of nocturnal cough, sleep quality, asthma control, and asthma attacks (2nd study stage). Details about nocturnal cough characteristics (1st study stage) will be published in a separate paper.¹⁵

The study has been reviewed and approved by the responsible ethics commission ("Ethikkommission Ostschweiz", ID: 2017–01872). All patients provided written informed consent. The study was conducted in accordance with the Declaration of Helsinki.

Study Subjects

Adult patients with a history of asthma (Figure 1) were included between February 2018 and June 2019 in two study centers in Switzerland (the Lung Center of the Cantonal Hospital St. Gallen and the mediX Group practice Zurich in cooperation with the University of Zurich).

No treatments were administered or prescribed by the study personnel. All patients were treated during the study period according to current medical knowledge and practice by their usual health-care partner.

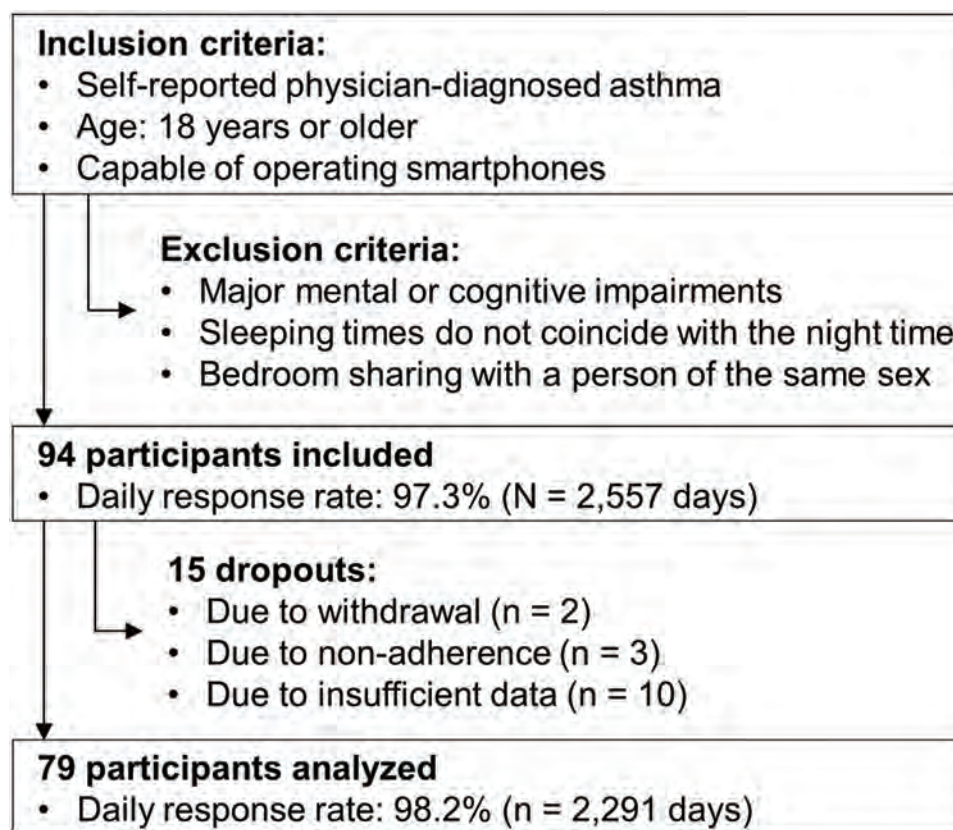

Figure 1 Study flowchart.

Study Design

Study duration per patient was 29 days. On d_1 and d_{29} , medical assessments of patients were performed at the study centers. In the time between study center appointments, questionnaire and sensor data were collected in situ with a smartphone (Samsung Galaxy A3 2017, SM-A320FL) application based on MobileCoach.^{16,17}

This work has four objectives: (1) to examine the statistical associations of both markers (ie, nocturnal cough and sleep quality) with asthma control, in particular with regard to within-patient associations; to investigate whether they enable detection of weeks, in which (2) patients had uncontrolled asthma or (3) clinically significant deteriorations in asthma control occurred; and (4) to explore whether they can be used to predict asthma attacks in advance.

The study was powered to examine statistical associations between both markers and asthma control.¹⁴ Data from 79 patients could be analyzed after accounting for dropouts, so that the targeted sample size was missed by 6 patients (Figure 1). Since the power analysis was based on conservative assumptions (ie, disregard of longitudinal measurements), the slightly smaller sample size likely sufficed for statistical analysis.

Measures

The study protocol¹⁴ contains a description of all measures we have obtained in the four study weeks per patient. Additional information on predictors and endpoints is provided in the online supplement (Supplementary Text S1).

Predictors

A patient's sleep quality was assessed daily via an adapted version of the Pittsburgh Sleep Quality Index (PSQI¹⁸). Although devices for assessing sleep quality passively and with a higher temporal resolution are available,¹⁹ we decided to use a questionnaire-based assessment to reduce the burden for patients during the study (ie, patients had to fill out questions on the smartphone every morning either way). PSQI score was standardized on a scale from 0 (worst possible sleep quality) to 1 (best possible sleep quality). In 2291 nights, the 79 patients slept rather well with an average sleep quality of 77.5% (SD = 15.2%; cf. Figure s1 in the online supplement for the distribution of average sleep quality scores per patient). Patients have completed the PSQI for 2250 nights (98.2%). For missing values, the patient mean was imputed (cf. Table s1 in the

online supplement for the benchmarking of different imputation methods).

Nocturnal cough frequencies of patients were obtained for every night by manually labelling audio recordings from the smartphone's built-in microphone. On average, patients coughed 9.9 times per night (SD = 27.1) with a median of 1 c/n (IQR 0–8). Figure s2 in the online supplement provides an illustration of the distribution of the average nocturnal cough count per patient. Data were available for 2145 out of 2212 nights (97.0%). Missing values were imputed by means of a Kalman Smoother.

Endpoints

Primary endpoint was asthma control. A weekly version of the ACT⁶ assessed a patient's level of asthma control retrospectively for a given week. Thus, four ACT measurements per patient were obtained. We observed statistically significant differences in ACT scores between seasons (Kruskal–Wallis' $H(3) = 8.76$, $p = 0.03$): The lowest (worst) average scores occurred between February and April ($M = 18.9$, $SD = 1.83$), while the highest (best) scores were reported between November and January ($M = 21.5$, $SD = 1.29$). Please refer to the online supplement for more information on seasonality, also with regard to the predictors (cf. Figures s3 – s5).

For the analysis of statistical associations (ie, objective (1) of the study), the raw ACT score was used. For objective (2), asthma was considered uncontrolled in weeks in which patients had an ACT score below 20 points.²⁰ The target outcome of objective (3) was defined according to the minimally important difference of the ACT: a decrease of >2 points in the ACT was considered a clinically meaningful deterioration in asthma control.²¹

Secondary endpoint was asthma attack days indicated through a “yes/no” questions for each day. Prior research has used “yes/no” questions for the self-reports of both asthma attacks²² and symptoms²³ before. Both endpoints were reported by patients at the end of each study week, ie, on d_8 , d_{15} , d_{22} , and d_{29} .

Data for the primary and secondary endpoint were available for 308 out of 316 study weeks (97.5%). No imputations were performed with regard to the endpoints.

Analysis

All data analyses were performed in R 3.5.1.^{24–28} Additional information, including a table summarizing the analysis plan, is available in the online supplement (cf. Tables s2 and s3).

For the analysis of objective (1) to (3), predictors were transformed and aggregated according to the ACT recall week, implying that predictors and outcome stem from the same time frame. For objective (4), days with asthma attacks were predicted with measurements from preceding days. Thus, predictions in a strictly temporal sense were only made in the context of objective (4).

Mixed-effects regressions²⁷ were employed in the analysis of objective (1).

For the analysis of objective (2) and (3), decision trees based on recursive partitioning analysis^{29,30} were applied. Detections were internally validated with a 5-fold cross-validation scheme.³¹

For objective (4), optimal cut-offs of predictor variable values were identified for attack prediction in the train folds and applied to each test fold, which represented an 8-fold cross-validation approach.

For objectives (2) to (4), averaged balanced accuracy (BAC; ie, mean of sensitivity and specificity) across all test folds (consisting of patients previously not seen by the model) was defined as the main evaluation metric. We further report sensitivity (ie, true positives/all positives) and specificity (ie, true negatives/all negatives).³²

Data Sharing Statement

It is not intended to share individual participant data.

Results

Table 1 summarizes the baseline characteristics of the 94 included patients.

Asthma Control and Asthma Attacks

For the analysis of statistical associations, raw ACT scores were considered. The 79 analyzed patients had a median

(Continued)

As the second objective, weeks with uncontrolled asthma were detected. Asthma was controlled in 192 weeks and uncontrolled in 116 weeks.

As the third objective, weeks with deteriorations in asthma control were detected. Changes in weekly asthma control could be calculated for 227 weeks. Clinically significant deteriorations occurred in 29 weeks in 25 patients.

Finally, the fourth objective was to investigate the prediction of asthma attacks. Twelve patients registered 35 attack days (mean = 2.9 days, SD = 2.5). Eight asthma attacks remained in a total of 2004 study days after keeping only the first attack day per patient and excluding all patients with attacks in the first study week.

Objective 1: Statistical Associations of Nocturnal Cough and Sleep Quality with Asthma Control Using Mixed Effect Regression Modelling

All regression coefficients, regardless of variable centering, were statistically significantly associated with asthma control ($p < 0.05$; cf. Table 2). Thus, patients, who coughed more/had worse sleep quality, tended to have worse asthma control (between-patient) and increases in nocturnal cough/decreases in sleep quality were statistically associated with decreases in asthma control in the

Table 2 Statistical Associations of Nocturnal Cough and Sleep Quality with Asthma Control Using Mixed Effect Regression Modelling

	Dependent Variable: Asthma Control Test Score		
	(1)	(2)	(3)
Nocturnal cough (between-patient)	-.87*** [-1.29, -.44]		-.51* [-.92, -.11]
Nocturnal cough (within-patient)	-.46*** [-.71, -.21]		-.41** [-.66, -.16]
Sleep quality (between-patient)		-2.71*** [-3.64, -1.77]	-2.26*** [-3.23, -1.30]
Sleep quality (within-patient)		-1.01** [-1.66, -.36]	-.85** [-1.49, -.21]
Marginal R ² ^a	0.14	0.25	0.29

Notes: Unstandardized beta (B) values are depicted. Square brackets contain the 95% confidence interval. Nocturnal cough values are weekly sums of the log-transformed cough count (a doubling of the weekly nocturnal cough frequency within a patient is associated with a decrease of 0.32/.28 points in the ACT test). Sleep quality are weekly sums of the inverted daily sleep quality score standardized from 0% to 100% (a weekly decrease of 100 points or an average daily decrease of 14.29 points within a patient is associated with a decrease of 1.01/.85 points in the ACT score). N = 308 weeks. ^aVariance explained by the predictors.³³ * $p < 0.05$. ** $p < 0.01$ *** $p < 0.001$.

same time and patient (within-patient). Interestingly, we have observed no statistical interaction between nocturnal cough and sleep quality when modelling their associations with asthma control ($B = -.14$, $t(271.34) = -1.06$, ns). Additional correlational analyses (Figure s7 for within-patient correlations between nocturnal cough and sleep quality and Figure s8 for correlations between cough based on subsegments of the night and asthma control; Supplementary Text S2) and the complete regression results table (Table s4) are available in the online supplement (Supplementary Text S3).

Objectives 2–4: Cross-Validated Models for the Detection or Prediction of Asthma Endpoints

Table 3 contains the results of all cross-validated models (additional result metrics can be found in Table s5 of the online supplement; also Supplementary Text S3). We considered cough of the first half hour of bedtime as a separate predictor set, since most coughs occurred in this time frame (a second paper contains a detailed discussion on the prevalence of nocturnal cough including possible explanations for the increased incidence of cough in the beginning of the night).¹⁵ We also included coughs of the remaining night (ie, after the first half hour of bedtime) as an additional predictor set. Since multiple variables have been used for growing the decision trees in objective (2) and (3), we facilitate model interpretation by providing estimates for the importance of each variable in the online supplement (Table s6).

For the second objective (ie, detection of weeks with uncontrolled asthma), we found that none of the five predictor sets achieved balanced accuracies of 70%. Sleep quality (BAC = 68%), however, was more useful for this objective than nocturnal cough (BAC = 60–62%). Combining predictor sets has not yielded an increase in prediction performance.

For the third objective (ie, detection of weeks with clinically meaningful deteriorations in asthma control), the pattern was inverted: Nocturnal cough (BAC = 71%) outperformed sleep quality (BAC = 56%) by a considerable margin. Interestingly, coughs within the first half hour of bedtime performed substantially worse than the entire night of cough ($\Delta\text{BAC} = -17\%$), while coughs after the first half hour of bedtime performed only slightly worse than the entire night ($\Delta\text{BAC} = -6\%$). Furthermore, combining predictors resulted in a decreased monitoring performance in comparison to nocturnal cough of the entire night.

Notes: All reported figures are averages over the five (O2 and O3) or eight (O4) folds. ^aModel: Decision Tree. ^bPositive outcome class: Uncontrolled asthma (ie, ACT score < 20; 116 out of 308 study weeks). ^cPositive outcome class: Clinically meaningful deterioration in asthma control (ie, a decrease in ACT score by > 2 points; 29 out of 227 study weeks). ^dModel: Cut-offs. ^ePositive outcome class: Asthma attack (ie, 8 out of 2008 study days). ACT, Asthma Control Test. BAC, Balanced accuracy (values over 0.70, a threshold for usefulness,³⁴ are printed in bold).

Abbreviation: O, objective.

The fourth objective was prediction of asthma attacks. BACs of 70% were achieved for subsegments of nocturnal cough three and four days ahead of the attack. Sleep quality was close to a BAC of 70% three to four days ahead of the attack. Combining predictor sets increased prognostic performance, regardless whether cough of the entire night (BACs of $\geq 70\%$ for $d_0 - d_{-4}$; cf. Figure 2A) or cough within (BACs of $\geq 70\%$ for $d_{-3} - d_{-5}$; cf. Figure 2B)

or after (BACs of $\geq 70\%$ for d_0 and $d_{-2} - d_{-4}$; cf. Figure 2C) the first half hour of bedtime was considered.

Discussion

In this study, smartphone-recorded nocturnal cough and sleep quality were systematically investigated as markers for asthma control and asthma attacks. We found that both markers could be potentially useful for monitoring asthma

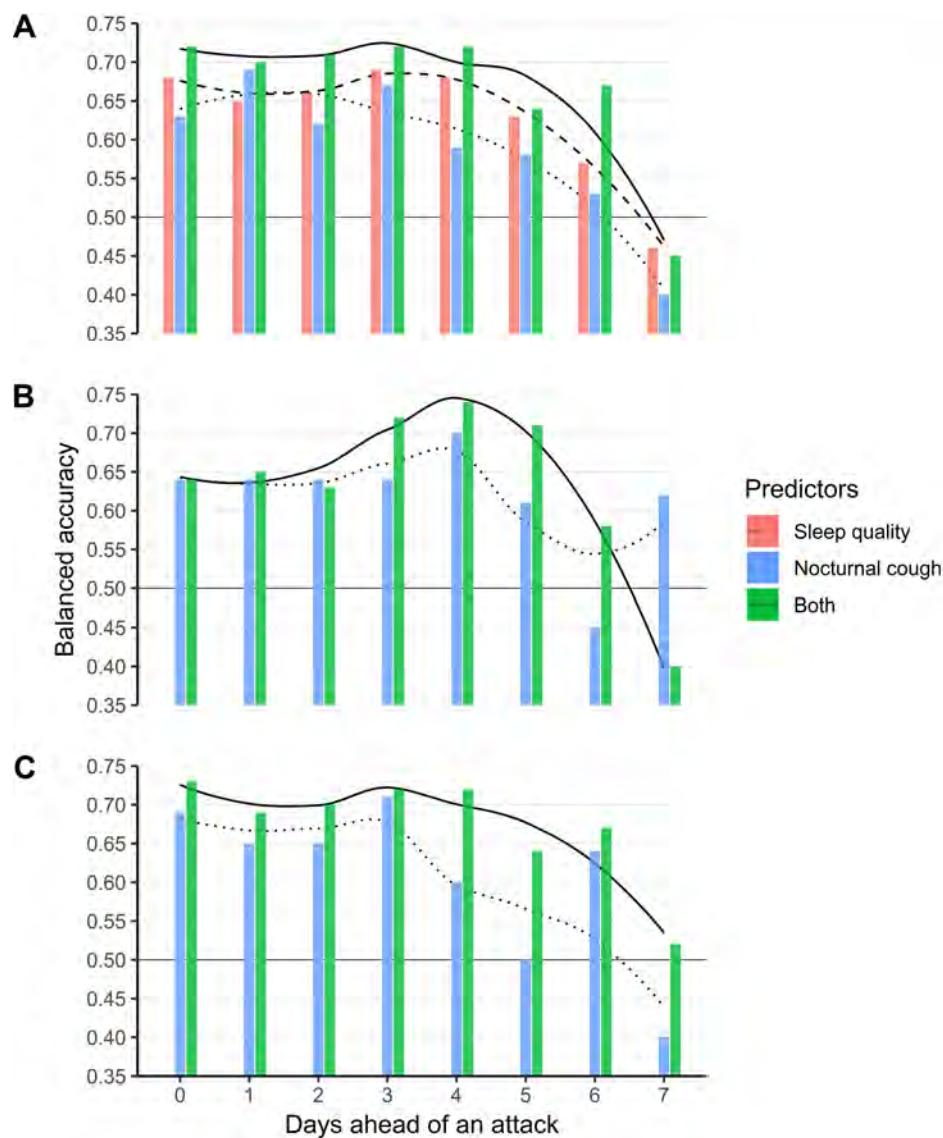

Figure 2 Asthma attack prediction results of cut-offs based on the entire night (A), cough of first 30 minutes of bedtime (B), and cough after 30 minutes of bedtime (C). No subsegments of the night could be extracted for sleep quality. Trend lines were estimated through local polynomial regression. Black lines at 0.50 indicate the balanced accuracy of a model that always predicts the same class.

control. Combining both markers enhanced prognostic performance up to five days ahead of an asthma attack.

We replicated the between-patient statistical associations of nocturnal cough and sleep quality with asthma control reported by prior research. Marsden et al described weak to moderate correlations between nocturnal cough of a single night and asthma control.¹¹ Luyster and colleagues have found similar cross-sectional correlation strengths with regard to sleep quality.¹⁰ With longitudinal data, however, we found stronger associations and were able to show that they hold for the within-patient level.

Our declining asthma attack prediction performance over time converges with prior descriptions of symptom

deteriorations in developing asthma attacks. Tattersfield and colleagues descriptively investigated 425 severe attacks in the two weeks prior to the attack.³⁵ A decline in symptoms and peak expiratory flow (PEF) “occurred gradually between day -10 and day -3 and then more rapidly”.

From a clinical point of view, long-term goals of asthma management are symptom control and risk reduction of asthma exacerbations and asthma-related deaths.² Asthma attacks can be fatal and are more common and more severe when asthma is not well controlled. Regular, objective assessment of asthma control is therefore a key element of successful asthma management. By recording markers of asthma control effortless and patient-friendly,

for example, via a smartphone as employed in this study, access to objective assessments of asthma control can be facilitated. For example, we were able to show that deep learning models trained on data from this study can detect and count nocturnal cough automatically with a comparable accuracy to human annotators.³⁶

However, the accuracies presented in this paper for detecting and predicting relevant asthma outcomes do not warrant the use of nocturnal cough and sleep quality as self-contained biomarkers for asthma management. The limiting factors for marker performance remain unclear. Possible reasons are the pragmatic study design with a limited study duration per patient and a smartphone-based data collection that is prone to operating errors, a sample characterized by rather well-controlled and intermittent-to-mild asthma, and disease-related reasons such as asthma's heterogeneity,³ which could limit marker applicability for certain asthma phenotypes and would result in an overall decreased marker performance if applied to the entire patient population.

Despite the moderate accuracies of our detection and prediction models based on nocturnal cough and sleep quality, we argue that both markers may be useful for asthma self-management. As part of its overall objective of increasing asthma control and preventing attacks, the GINA guideline recommends patients to monitor their symptoms.² The associations with asthma outcomes reported in this paper suggest that nocturnal cough and sleep quality may indeed be relevant parameters for asthma symptom self-monitoring. Furthermore, their moderate accuracies as self-contained biomarkers could be offset if assessments are subsequently confirmed by more accurate methods. Honkoop and colleagues found that action points based on PEF and symptom questionnaires enabled highly accurate early detection of asthma attacks.³⁷ Thus, passively measured nocturnal cough and sleep quality could serve as additional cues for active monitoring based on action points. More specifically, objective cues for initiating active monitoring could enrich patients' subjective self-assessments, which have been reported to be biased.⁵ Future research should investigate the efficacy and effectiveness of such a two-stage monitoring strategy empirically. In the long-term application of both markers in practice, we suspect that nocturnal cough might emerge as the more robust and useful marker due to its inherently higher specificity to the respiratory system and due to a possible confounding treatment effect of oral corticosteroids (improvement in asthma outcomes² accompanied by a simultaneous impairment of sleep quality).³⁸

Strengths and Limitations

This is the first longitudinal study to examine the utility of nocturnal cough and sleep quality as markers for asthma. By defining lenient eligibility criteria and collecting patient data in situ, the presented results are characterized by high external validity. In a more controlled setting, we would expect higher performance figures due to more reliable measurements. Furthermore, by taking advantage of prior research on ACT cut-offs for different classification purposes,^{20,21} we were able to investigate the utility of both candidate markers from multiple perspectives.

However, high external validity comes at the expense of compromised internal validity: we included patients with self-reported physician-diagnosed asthma and modelled patients' subjective assessments, which likely introduced noise into our analysis, for example, due to varying definitions of asthma attacks between patients. Finally, the prognostic performance results have to be interpreted cautiously due to the low number of observed asthma attacks.

Acknowledgments

We thank all patients who participated in this study. Further, we thank the study teams of all participating institutions for their support.

Parts of this paper have been presented as an oral presentation and e-poster at the International Congress of the European Respiratory Society (05. – 09.09.2020) and as an oral presentation at the annual congress of the Swiss Society for Pulmonology (23.09.2020).

Journal of Asthma and Allergy

Dovepress

Publish your work in this journal

The Journal of Asthma and Allergy is an international, peer-reviewed open-access journal publishing original research, reports, editorials and commentaries on the following topics: Asthma; Pulmonary physiology; Asthma related clinical health; Clinical immunology and the immunological basis of disease; Pharmacological interventions and

new therapies. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/journal-of-asthma-and-allergy-journal>
